(Dated: January 20, 2013)

We consider the quintic one dimensional nonlinear Schrödinger equation with forcing and both linear and nonlinear dissipation. Quintic nonlinearity results in multiple collapse events randomly distributed in space and time forming forced turbulence. Without dissipation each of these collapses produces finite time singularity but dissipative terms prevents actual formation of singularity. In statistical steady state of the developed turbulence the spatial correlation function has a universal form with the correlation length determined by the modulational instability scale. The amplitude fluctuations at that scale are nearly-Gaussian while the large amplitude tail of probability density function (PDF) is strongly non-Gaussian with power-like behavior. The small amplitude nearly-Gaussian fluctuations seed formation of large collapse events. The universal spatio-temporal form of these events together with the PDF for their maximum amplitudes define the power-like tail of PDF for large amplitude fluctuations, i.e., the intermittency of strong turbulence.

I. INTRODUCTION

A nonlinear Schrödinger equation (NLS)

$$i\psi_t + \nabla^2\psi + \alpha|\psi|^2\psi + \beta|\psi|^4\psi = 0, \quad (1)$$

describes a wide class of interacting nonlinear waves and Bose-Einstein condensates. Here t is the time, the Laplacian ∇^2 is considered in the general dimension D , the constants α and β correspond to the cubic and quintic nonlinearities, respectively. Generally, $\alpha|\psi|^2\psi$ gives the leading order nonlinear interaction. In many nonlinear systems α can vanish, which results in the quintic nonlinear Schrödinger equation (QNLS)

$$i\psi_t + \nabla^2\psi + \beta|\psi|^4\psi = 0. \quad (2)$$

QNLS occurs e.g., in the Bose-Einstein condensate where the s -wave scattering length is set to zero by tuning Feshbach resonance [1, 2]. QNLS also occurs for general NLS type system near the transition from supercritical to subcritical bifurcations [3, 4], pattern formation (in the context of quintic Ginzburg-Landau equation if β is the complex constant) [5] and dissipative solitons (e.g., in lasers) [6]. Another possible experimental realization of equation (2) is the optical pulse propagation in optical fiber using a nonlinear compensator of nonlinearity [7].

The standard cubic NLS (equation (1) with $\beta = 0$) is integrable in dimension one (1D) by the inverse scattering transform [8] with global existence of all solutions. In contrast, QNLS (2) with positive real β and any $D \geq 1$ can develop a finite time singularity (blow up) such that the amplitude of solution reaches infinity in a finite time. The blow up is accompanied by dramatic contraction of the function ψ spatial extent, that is called wave collapse or simply collapse [9, 10]. A sufficient condition for the collapse is $H < 0$, where

$$H = \int (|\nabla\psi|^2 - \frac{\beta}{3}|\psi|^6) d\mathbf{r} \quad (3)$$

is the Hamiltonian (energy) and the equation (2) can be rewritten in the Hamiltonian form

$$i\psi_t = \frac{\delta H}{\delta \psi^*}. \quad (4)$$

The case $D = 1$, which we consider below, is critical because any decrease of the power of nonlinearity in (2) (i.e., replacement of $|\psi|^4\psi$ by $|\psi|^{4+\gamma}\psi$, $\gamma < 0$) results in the global existence of the solutions [11–13] for any real β .

Collapse of QNLS is not physical and near singularity different physical regularization mechanisms come into play. These can be numerous nonlinear dissipation mechanisms such as inelastic collisions in Bose-Einstein condensate which results in loss of particles from the condensate [1], optical breakdown and formation of plasma in nonlinear optics [14], or numerous non-dissipative regularization effects such as nonlinear saturation in laser-plasma interactions [15], different dispersive effects or non-paraxiality of optical beam (see e.g., [16]).

In this paper we consider 1D QNLS with linear and nonlinear dissipation so that QNLS (2) is replaced by the following regularized QNLS (RQNLS):

$$i\psi_t + (1 - ia\epsilon)\partial_x^2\psi + (1 + ic\epsilon)|\psi|^4\psi = i\epsilon\phi, \quad (5)$$

which can be also called as a complex quintic Ginzburg-Landau equation. Here x is the spatial coordinate replacing general $\mathbf{r}$, $0 < \epsilon \ll 1$ is a small parameter so that to the leading approximation $\epsilon \rightarrow 0$, QNLS (2) is valid. The coefficient $a \sim 1$ determines linear dissipation and the coefficient $c \sim 1$ is responsible for nonlinear dissipation. The linear dissipation has a viscosity-like form and can be resulted, e.g., from angular-dependent losses or the optical filtering [17, 18]. The nonlinear dissipation in RQNLS corresponds to the three-photon absorption in optics [14] or four-body collisions which cause loss of atoms from the Bose-Einstein condensate [19]. The term

$i\epsilon\phi$ describes the general forcing in the system. The specific examples of the realization of RQNLS (5) are e.g., a propagation of light in a ring cavity with Kerr nonlinearity (see e.g., [20]) or any quite general propagation of waves in nonlinear media with complex dispersion and nonlinear dissipation [21].

The right hand side (rhs) of equation (5) provides forcing and depends on the specific physical model. We consider two types of forcing. First is a deterministic forcing

$$\phi = \hat{b}\psi, \quad (6)$$

which corresponds to a linear instability (amplification) in a system. Here $\hat{b}$ is the linear integral operator over x such that its spatial Fourier transform b_k is the multiplication operator $\phi_k = b_k\psi_k$, where b_k determines k -dependence of the amplification. Below, if not mentioned otherwise, we implicitly assume the simplest case of k -independent amplification as $\hat{b}\psi = b\psi$ and thus, the equation (6) takes the following form

$$\phi = b\psi, \quad (7)$$

where b is the positive constant.

The second type is a random additive forcing

$$\phi = \xi(t, x), \quad (8)$$

where zero in average stochastic term ξ is a random Gaussian variable which is δ -correlated in time and has a finite spatial correlation such that

$$\langle \xi(t_1, x_1) \xi^*(t_2, x_2) \rangle = \delta(t_1 - t_2) \chi(|x_1 - x_2|). \quad (9)$$

Here

$$\chi(|x_1 - x_2|) = b_g \exp[-|x_1 - x_2|/l_c], \quad (10)$$

l_c is the correlation length of pump, $\langle \dots \rangle$ denotes averaging over the statistics of ξ , and b_g is the normalization constant.

Forcing results in the pumping of energy into the system described by RQNLS and subsequent formation of multiple collapse events randomly distributed in space and time as shown in Figure 1a. Figure 1b shows a zoom-in into a temporal evolution of a spatial profile of a typical collapse event which involves growth and subsequent decay of collapse amplitude.

After the initial transient, the solution of RQNLS achieves a statistical steady state (i.e., state of the developed turbulence) as shown in Figure 2 through the time dependence of the following integral

$$N = \int |\psi|^2 dx, \quad (11)$$

which has a meaning either of the number of particles in Bose-Einstein condensate, or an optical power (or sometimes energy) in optics as well as it is called by a wave action in oceanology and many other nonlinear wave applications [21]. Below we refer to N as the number of

FIG. 1: (Color online) Spatial-temporal form of solution of RQNLS (5) with the deterministic forcing (7), $b = 10^4$, $\epsilon = 2 \times 10^{-3}$, and $a = c = 1$ for different moments of time. (a) Collapses (seen in plot as sharp peaks) occur at random spatial positions and random times. (b) Zoom-in at evolution of single collapse event is shown for the smaller time interval and the smaller spatial extent compare with (a). It is seen that the collapse amplitude grows initially, then goes through the maximum and finally decays due to dissipative effects. Colors are added to (a) and (b) to help distinguish different moments of time.

particles. It is seen in Figure 2b that the dissipation is important near large collapses while forcing works all time (because forcing is $\propto N$). In the statistical steady state the pumping of particles (forcing) in average is compensated by the dissipation which insures the state of the developed turbulence.

The focus of this paper is to describe the strong turbulence in RQNLS characterized by these nearly-singular collapse events. By strong turbulence (we also call it strong collapse turbulence) we mean the turbulence with strong non-Gaussian fluctuations as opposed to the weak turbulence with nearly Gaussian fluctuations [21]. The strong non-Gaussian fluctuations are usually refer to as

FIG. 2: (Color online) Time dependence of the number of particles N for numerical simulation of RQNLS (5) with the deterministic forcing (7) (left axis, thick solid line) superimposed with the time evolution of maximum value of $|\psi|$ (right axis, solid line). Parameters are $b = 10^4$, $a = c = 1$, $\epsilon = 2 \times 10^{-3}$ and the random small amplitude initial condition is used. (a) Initially N grows until the statistical steady-state of developed turbulence is achieved so that N remains constant in average over time. (b) Zoom-in at the smaller scale in t . Solid thick curve (blue) corresponds to $N(t)$. Solid thin curve (green) shows time dependence of maximal spatial value of $|\psi|$. Scale for N is on the left vertical axis and scale for $\max |\psi|$ is on the right vertical axis, respectively. It is seen that sharp decreases of N is due to the dissipation from large collapses. These decreases are compensated in average by growth of N from the linear forcing.

intermittency of turbulence [22]. The classical example of the strong turbulence is the Navier-Stokes turbulence. The old idea of the description of strong turbulence in the Navier-Stokes equations through singularities of the Euler equations still remains unsolved [22]. The forced Burgers equation is a very rare example of an analytical description of strong turbulence in which the tail of the probability density function (PDF) for negative gradients follows a well-established $(-7/2)$ power law [23], dominated by the spatio-temporal dynamics near formation of singular shocks (i.e., by pre-shocks). The spectrum of the strong optical turbulence was considered for the two-dimensional cubic nonlinear Schrödinger equation in Ref. [24] and power law tail of PDF of the amplitude fluctuations was considered in Refs. [25] and [26]. Strong turbulence in RQNLS was first studied in Refs. [27] and [28] with the (-8) PDF power law scaling suggested in Ref. [27]. Here we show that (-8) is only an approximate scaling and it is determined by fluctuations of the waves at background which seed collapses as well as by the self-similar form of collapsing solutions. We also found that the power law of PDF tail is only weakly sensitive to the type of forcing (linear amplification (7) vs. additive random forcing (8)) for $\epsilon \ll 1$ showing the universal turbulent picture.

The paper is organized as follows. In Section II we consider the small amplitude fluctuations of the background of RQNLS turbulence, and show the universality of the spatial and temporal correlation functions and relate the correlation scale of these fluctuations to the scale of the modulational instability. In Section III we review the collapsing self-similar solution of RQNLS for $\epsilon = 0$ and establish the universality of the self-similar solution for $\epsilon \neq 0$ as a basic building block for large amplitude fluctuations. In Section IV A we provide the results of numerical calculations of PDF for the amplitude fluctuations and for the collapse maximums. In Section IV B we derive the analytical expression for the tail of PDF for amplitudes and compare with numerics. In Section V we discuss the details of the numerical methods used. In Section VI the main results of the paper and future directions are discussed.

II. MODULATIONAL INSTABILITY AND FLUCTUATIONS OF THE BACKGROUND

The forcing term in right hand side (rhs) of RQNLS (5) pumps the number of particles N into the system until the statistical steady state (also can be called by a developed turbulence state) is reached as shown in Figure 2a for the particular example of the deterministic forcing (7). The system in developed turbulence state does not have memory of initial conditions because of the modulational instability. That instability was derived for the cubic NLS [29] (see also e.g. [21]) but it is straightforward to generalize it for RQNLS as follows. RQNLS (5) with $\epsilon = 0$ has a spatially uniform

solution $\psi = \psi_0 \exp(i|\psi_0|^4 t)$. Linearization on the background of that solution in the form $\psi = \exp(i|\psi_0|^4 t)[\psi_0 + \delta\psi \exp(\nu t + i k x)]$ with $|\delta\psi/\psi_0| \ll 1$ gives the following instability growth rate ν for the wavenumber k :

$$\nu^2 = k^2(4|\psi_0|^4 - k^2). \quad (12)$$

The instability occurs for $|k| < 2|\psi_0|^2$ with the unstable branch $\text{Re}(\nu(k)) = \nu(k) > 0$ reaching maximum of $\nu(k)$ for

$$k_{max}^2 = 2|\psi_0|^4. \quad (13)$$

For $\epsilon \neq 0$, the expressions (12) and (13) are still approximately valid provided $\nu(k_{max}) = 2|\psi_0|^4 \gg 1/\tau_f$, where τ_f is the typical time of forcing. For the deterministic forcing (7), $\tau_f = (\epsilon b)^{-1}$ while for the stochastic forcing (8), τ_f can be estimated from the condition that dissipation in average is compensated by the forcing. Then $\tau_f \sim \min[(\epsilon c p_0^4)^{-1}, (\epsilon a k_0^2)^{-1}]$, where p_0 is the typical amplitude of the fluctuation of $|\psi|$ and k_0 is the typical wavevector which is estimated from (13) as $k_0 \sim k_{max}$. Recalling now our assumption that $a \sim 1$ and $c \sim 1$ we arrive to a simpler estimate $\tau_f \sim (\epsilon p_0^4)^{-1}$, e.g., using the parameters of Figure 2 we obtain that $1/\tau_f \simeq 20 \ll \nu(k_{max}) \simeq 3 \cdot 10^2$.

Thus the dynamics of the background of turbulence can be characterized by the typical amplitude of the fluctuations p_0 and spatial scale $1/k_{max} = 1/(2^{1/2}p_0^2)$. For simulations we define $p_0 = (N/L_0)^{1/2}$, where $L_0 = \int dx$ is the computational domain (without loss of generality we set $L_0 = 1$ in our simulations as described in Section V). We determine a correlation length x_{corr} of ψ through the full width at half maximum (FWHM) of the spatial correlation function $S(x) = \langle \psi(x_0, t) \psi^*(x_0 + x) \rangle$. Here, $\langle \dots \rangle$ denotes averaging over space and time which is assumed by the ergodicity to give the same result as the average over the ensemble of simulations. Figure 3 shows $|S(x)/S(0)|$ vs. x/x_{corr} for a set of simulations with different sets of parameters. Each curve is calculated in the statistical steady state. It is seen that $|S(x)/S(0)|$ is well approximated by the universal function of x/x_{corr} which is close to a Gaussian function $\exp[-(x/x_0)^2]$ while $S(0) = p_0^2$ and x_0 is chosen from the condition to have the same FWHM of the Gaussian function and $|S(x)/S(0)|$. It implies $x_0/x_{corr} = 1/(2\sqrt{\ln 2})$. Note with the increase of the ensemble of simulations (i.e., the simulation time used to calculate $S(x)$), the value of $\text{Im}(S(x))$ approaches to 0.

We also determine a correlation time t_{corr} of ψ through FWHM of the temporal correlation function $P(t) = \langle \psi(x, t_0) \psi^*(x, t_0 + t) \rangle$. Figure 4 shows $|P(t)/P(0)|$ as a function of normalized time t/t_{corr} calculated in the statistical steady state. It is seen that for different set of parameters, $|P(t)/P(0)|$ is well approximated by the universal function of t/t_{corr} . The fluctuations in the tails of $|P(t)/P(0)|$ in Figure 4 are due to the finite size of the statistical ensemble.

FIG. 3: (Color online) Absolute value of the normalized spatial correlation function $|S(x)/S(0)|$ vs. x/x_{corr} . Parameters are $\epsilon = 5 \cdot 10^{-3}, a = c = 1, b = 10^4$ (solid blue line), $\epsilon = 2 \cdot 10^{-3}, a = c = 1, b = 10^4$ (dashed-dotted blue line), $\epsilon = 10^{-3}, a = c = 1, b = 10^4$ (dashed blue line), $\epsilon = 2 \cdot 10^{-3}, a = c = 1, b = 2 \cdot 10^3$ (dotted blue line), $\epsilon = 2 \cdot 10^{-3}, a = 1, c = 2, b = 10^4$ (green crosses), and $\epsilon = 2 \cdot 10^{-3}, a = 2, c = 1, b = 10^4$ (light blue circles). Red squares correspond to a Gaussian function $\exp[-4 \ln 2 (x/x_{corr})^2]$ which has a unit FWHM.

FIG. 4: (Color online) Absolute value of the normalized temporal correlation function $|P(t)/P(0)|$ vs. t/t_{corr} . Parameters are $\epsilon = 5 \cdot 10^{-3}, a = c = 1, b = 10^4$ (green circles), $\epsilon = 2 \cdot 10^{-3}, a = c = 1, b = 10^4$ (dashed-dotted blue line), $\epsilon = 10^{-3}, a = c = 1, b = 10^4$ (dashed blue line), $\epsilon = 2 \cdot 10^{-3}, a = c = 1, b = 2 \cdot 10^3$ (dotted blue line), $\epsilon = 2 \cdot 10^{-3}, a = 1, c = 2, b = 10^4$ (red crosses), and $\epsilon = 2 \cdot 10^{-3}, a = 2, c = 1, b = 10^4$ (solid blue line).

FIG. 5: (Color online) Dependence of p_0^2 on x_{corr}^{-1} , where x_{corr} is the FWHM of spatial correlation function $S(x)$. Circles correspond to the case of k -independent deterministic forcing with $a = 1, b = 10^3, c = 1, \epsilon = 2 \cdot 10^{-3}$; $a = 1, b = 2 \cdot 10^3, c = 1, \epsilon = 2 \cdot 10^{-3}$; $a = 1, b = 3 \cdot 10^3, c = 1, \epsilon = 2 \cdot 10^{-3}$; $a = 2, b = 10^4, c = 1, \epsilon = 2 \cdot 10^{-3}$; $a = 1, b = 10^4, c = 2, \epsilon = 2 \cdot 10^{-3}$; $a = 1, b = 10^4, c = 1, \epsilon = 5 \cdot 10^{-3}$, from leftmost to rightmost. Squares are for the “ k -limited” deterministic forcing (6), (15) with $k_{cutoff} = 10\pi$ for $a = 1, b = 10^3, c = 1, \epsilon = 2 \cdot 10^{-3}$; $a = 1, b = 3 \cdot 10^3, c = 1, \epsilon = 2 \cdot 10^{-3}$; $a = 2, b = 10^4, c = 1, \epsilon = 2 \cdot 10^{-3}$; $a = 1, b = 10^4, c = 2, \epsilon = 2 \cdot 10^{-3}$; $a = 1, b = 10^4, c = 1, \epsilon = 5 \cdot 10^{-3}$, from leftmost to rightmost. Diamonds are for the random forcing with $a = 1, b_g = 250, c = 1, \epsilon = 5 \cdot 10^{-3}$; $a = 1, b_g = 1250, c = 1, \epsilon = 5 \cdot 10^{-3}$; $a = 1, b_g = 1250, c = 1, \epsilon = 2 \cdot 10^{-3}$; $a = 1, b_g = 2500, c = 1, \epsilon = 2 \cdot 10^{-3}$; $a = 2, b_g = 5000, c = 1, \epsilon = 2 \cdot 10^{-3}$; $a = 1, b_g = 5000, c = 2, \epsilon = 2 \cdot 10^{-3}$; $a = 1, b_g = 5000, c = 1, \epsilon = 2 \cdot 10^{-3}$, and $l_c = 0.02$ in all cases from leftmost to rightmost. Solid line has a slope 0.48 in accordance with (14).

Figure 5 shows that the dependence of $p_0(x_{corr})$ is well approximated by

$$p_0^2 x_{corr} = \text{Const} \simeq 0.48 \quad (14)$$

for different values of parameters of RQNLS and for 3 different types of forcing. This gives another indication that the modulational instability determines the correlation length x_{corr} through the amplitude of the background fluctuations p_0 in agreement with the equation (13).

Here, the first type is the standard forcing (7) which, while not introducing any scale by itself (it pumps energy into all Fourier modes k), creates the scale x_{corr} indirectly through the development of the modulational instability. Circles in Figure 5 correspond to that type of forcing.

The second type is a particular example of the general type of forcing (6). We define it by introducing a cutoff wave number k_{cutoff} for the amplification:

$$b_k = b_0 \neq 0, \quad |k| \leq k_{cutoff}; \quad b_k = 0, \quad |k| > k_{cutoff}. \quad (15)$$

FIG. 6: Time dependence of the number of particles N in the case of “ k -limited” deterministic forcing (6),(15) with $k_{cutoff} = 10\pi$. Parameters are $a = c = 1, b_0 = 10^4, \epsilon = 2 \cdot 10^{-3}$.

FIG. 7: Time dependence of the number of particles N in the case of random forcing. Parameters are $a = c = 1, \epsilon = 10^{-3}, l_c = 0.02, b_g = 12500$.

In Figures 5,6, for this second type of forcing we use (6) and (15) with $k_{cutoff} = 10\pi$ which means that only 11 modes are amplified. The resulting $N(t)$ dependence in Figure 6 is similar to Figure 2. In simulation of Figure 6, $k_{max} \simeq 2p_0^2 \simeq 20 \sim k_{max}$, and thus, $k_{cutoff} \sim k_{max}$. Squares in Figure 5 correspond to this type of forcing.

The third type is a random additive forcing (8). Figure 7 shows $N(t)$ dependence from the simulations with a random forcing and the result is similar to Figures 2 and 6. Diamonds in Figure 5 correspond to this type of forcing.

We conclude that the turbulence in RQNLS is inde-

pendent of the type of forcing used (up to the normalization). The own scale of the forcing (if exist) is not important and the correlation length is determined by the modulational instability scale. Qualitative picture is the following: the interplay between forcing and dissipation in RQNLS defines the amplitude p_0 and the correlation length x_{corr} to be related by (14).

We also note that the principle difference between RQNLS turbulence and Navier-Stokes turbulence is the absence for RQNLS of well-defined inertial interval at which both forcing and dissipation are not important. For RQNLS dissipation and forcing generally act at all scales. Thus study of the spectrum of $\langle |\psi_k|^2 \rangle$ could give much less information compare with e.g., weak turbulence [21]. Instead below we focus on the study of the tail of PDF for large fluctuations.

III. COLLAPSE AND ITS REGULARIZATION IN RQNLS

Fluctuations of background result in multiple formations of collapses in RQNLS as shown in Figure 1. For $\epsilon = 0$, the collapsing solution of RQNLS has the following self-similar form

$$\psi(r, t) = \frac{1}{L^{1/2}} V(\rho, \tau) e^{i\tau + iLL_t \rho^2/4}, \quad (16)$$

$$\rho = \frac{r}{L}, \quad \tau = \int^t \frac{dt'}{L^2(t')},$$

where $L = L(t)$ is the dynamically evolving spatial scale of the collapsing solution at a given moment of time, ρ and τ are sometimes called by blow up variables. $V(\rho, \tau)$ is well approximated for small $L \ll 1$ by the ground state soliton solution $R_0(\rho) : V(\rho, \tau) \simeq R_0(\rho)$. Here $R_0(x)$ is the positive-definite solution of the equation $-R_0 + \partial_x^2 R_0 + R_0^3 = 0$, which follows from RQNLS assuming that $\psi = e^{it} R_0(x)$ and $\epsilon = 0$. The explicit expression for $R_0(x)$ is given by

$$R_0(x) = \frac{3^{1/4}}{(\cosh 2x)^{1/2}}. \quad (17)$$

The Hamiltonian (4) ($\beta = 1$ according to (5)) vanishes at the ground state soliton solution (17). The number of particles (11) at (17) is given by

$$N_c = \frac{\sqrt{3}\pi}{2}. \quad (18)$$

N_c determines the boundary between collapsing and non-collapsing solutions: collapse is impossible for $N < N_c$. Note that the ground state soliton solution for NLS (1) with $\beta = 0$ in dimension two (2D) is often referred to as the Townes solution and it plays a similar role to (17) in the collapse of 2D NLS. As $L(t)$ decreases with $t \rightarrow t_0$, the spatial distribution of $V(\rho) \rightarrow R(\rho)$ for $\rho \lesssim 1$, where t_0 is the collapse time (time at which a singularity develops in the solution of RQNLS with $\epsilon = 0$). It implies that the number of particles in the collapsing region,

$N_{collapse} \rightarrow N_c$ as $t \rightarrow t_0$, i.e., the collapse of QNLS is strong one as opposed to the weak collapse [13, 30] for which the number of particles in the collapsing region vanishes as $t \rightarrow t_0$.

The leading order behavior of $L(t)$ for $t \rightarrow t_0$ can be estimated from the scaling analysis as $L(t) \sim (t_0 - t)^{1/2}$ but the criticality of 1D QNLS results in the following log-log modification of that scaling [24, 31–33]

$$L \simeq \left(\frac{2\pi(t_0 - t)}{\ln \ln[1/(t_0 - t)]} \right)^{1/2}. \quad (19)$$

RQNLS with $\epsilon > 0$ does not allow singular collapses. Instead, for $0 < \epsilon \ll 1$, the collapse amplitude $|\psi|_{max}(t) \equiv \max_x |\psi(x, t)|$ goes (as a function of time) through a maximum $|\psi|_{maxmax} = \max_t |\psi|_{max}(t)$ at some $t = t_{max}$ and decays after that as shown in Figure 8a. The spatial form of the collapsing solution is still well approximated by (16) and (17) before and shortly after $t = t_{max}$ as seen in Figures 9a,b and c. It is seen in Figure 9a that with the growth of $|\psi|_{max}(t)$ the normalized shape of solution approaches to (17). But with the decay of $|\psi|_{max}(t)$ for $t > t_{max}$, the normalized shape of solution departs from (17) and produces growing oscillating tails as seen in Figures 9b and 9c. In the vicinity of $t = t_{max}$ the forcing on the rhs of RQNLS (5) can be neglected. The resulting equation can be written in rescaled units $t|\psi|_{maxmax}^4$, $x|\psi|_{maxmax}^2$, and $\psi/|\psi|_{maxmax}$ to have exactly the same form, i.e., RQNLS without forcing is invariant with respect to these scaling transformations. As shown in Figure 8b vs. Figure 8a, $|\psi|_{max}(t)$ rescaled in these units exhibits a universal behavior: all curves collapse on a single curve in the neighborhood of large collapses. That universality is independent of the complicated structure of optical turbulence. We conclude up to rescaling all collapse events in RQNLS are identical which is qualitatively similar to the universality of collapse in QNLS. This universality is a characteristic feature of the dissipative terms in RQNLS (5).

A function

$$\gamma \equiv -L \frac{dL}{dt}, \quad (20)$$

changes slowly with t compared to L at $t \lesssim t_{max}$ except very small neighborhood of $t = t_{max}$ as shown in Figure 10. The dependence of $\gamma(t)$ is shown in Figure 10 in the rescale time unit $(t - t_{max})|\psi|_{maxmax}^4$ similar to Figure 8b. We determine $L(t)$ numerically from individual collapse events with $|\psi|_{maxmax} > 30$ using (16) and (17) as $L(t) = 3^{1/2}/|\psi|_{max}(t)^2$. Thus, the universality of each collapse event is seen for $\gamma(t)$ also.

We conclude in this Section that the collapse events in RQNLS turbulence are all universal ones after a proper rescaling.

FIG. 8: (Color online) (a) Dependence of $|\psi|_{\max}$ on $(t - t_{\max})$. 75 individual collapse events are collected for $|\psi|_{\max} \geq 15$ with parameters $a = 1, b = 10^4, c = 1, \epsilon = 2 \cdot 10^{-3}$. (b) The same dependence as in (a) but in rescaled units $(t - t_{\max})|\psi|_{\max\max}^4$ and $|\psi|_{\max}/|\psi|_{\max\max}$. The time intervals over which $|\psi|_{\max}/|\psi|_{\max\max}$ are plotted correspond to the time intervals of (a) (i.e., temporal interval is fixed in non-rescaled units). As a result, collapses with relatively small $|\psi|_{\max\max}$ extends over small intervals of $(t - t_{\max})|\psi|_{\max\max}^4$ in (b).

IV. PDF OF $|\psi|$

A. PDFs from simulations

Once the amplitude of a collapse event $|\psi|_{\max}$ reaches the maximum $|\psi|_{\max\max}$, it starts decreasing and subsequently, the collapse event decays into outgoing waves as seen in Figure 9b and 9c. Decaying waves are almost liner ones as can be seen from the time dependence of the

FIG. 9: (Color online) Scaled profiles of numerical solution $|\psi(x)|$ in the vicinity of $t = t_{\max}$ at which $|\psi|_{\max}$ reaches the maximum $|\psi|_{\max\max}$. Parameters are $\epsilon = 2 \cdot 10^{-3}, a = c = 1, b = 10^4$. (a) Scaled numerical solution $|\psi(x)|$ at $t = t_{\max} - (4 \cdot 10^{-5})$ (dotted red), $t = t_{\max} - 10^{-5}$ (dashed blue), and $t = t_{\max}$ (dashed-dotted green). Solid black line shows the normalized ground state soliton $\tilde{R}(\rho) = 3^{-1/4} R_0(\rho)$ (17). (b) Scaled numerical solution $|\psi(x)|$ at $t = t_{\max} - 10^{-8}$ (dotted red), $t = t_{\max}$ (dashed blue), $t = t_{\max} + 10^{-8}$ (dashed-dotted black), $t = t_{\max} + (7 \cdot 10^{-8})$ (solid green). Circles show the normalized ground state soliton as in (a). (c) Logarithmic scale of Figure (b).

FIG. 10: (Color online) Dependence of $\gamma(t) = -L_t L$ on $(t - t_{max})|\psi|_{max}^4$. The same individual collapse events as in Figure 8 are collected for $|\psi|_{max} \geq 30$ in non-rescaled units.

ratio of the kinetic energy $K = \int |\partial_x \psi|^2 dx$ and the potential energy $P = -\frac{1}{3} \int |\psi|^6 dx$ in Figure 11a. Note that the Hamiltonian (3) is a sum of K and P and during the growth of the amplitude $|\psi|_{max}$ of collapse event, these terms nearly cancel each other if the integrals are calculated only inside the collapsing region $\rho \lesssim 1$. While at the decay phase of the collapse event, the amplitude that balances is strongly violated in favor of K meaning that solution is becoming nearly linear one. Figure 11b shows zoom-in at a single collapse event. It is seen that while amplitude of collapse event decays, the kinetic energy from outgoing waves dominates over potential energy. Superposition of many of these almost linear waves from multiple collapse event forms a nearly random Gaussian field by the central limit theorem [34]. That random field seeds new collapse events.

Figure 12a shows PDF $\mathcal{P}_r(h_r)$ for the real part of the amplitude ψ to have a value h_r . PDF for the imaginary part of ψ has the same form. Solid line is the match to the Gaussian distribution (with the same variance as for $\mathcal{P}_r(h_r)$) which is almost indistinguishable from $\mathcal{P}_r(h_r)$. PDF $\mathcal{P}_r(h_r)$ is determined from simulations as

$$\mathcal{P}_r(h_r) = \frac{\int \delta(\text{Re}(\psi(x, t)) - h_r) dx dt}{\int dx dt}. \quad (21)$$

Here the integrals are taken over all values of x and all values of t after the turbulence has reached the statistically steady state. We assume ergodicity of turbulence, i.e., that averaging over space and time is equivalent to the averaging over ensemble of initial conditions (or the stochastic realizations of random forcing for the random forcing case).

In a similar way, $\mathcal{P}(h)$ for the amplitude $|\psi|$ to have a

FIG. 11: (Color online) (a) Time dependence of $\frac{K}{P}$, where K is the kinetic energy and P is the potential energy defined in the text. Parameters are $a = 1, b = 10^4, c = 1, \epsilon = 2 \cdot 10^{-3}$. Thick solid curve (blue) corresponds to $\frac{K}{P}$. Thin solid curve (green) is time dependence of maximal spatial value of $|\psi|$. Scale for $\frac{K}{P}$ is on the left vertical axis and scale for $\max |\psi|$ is on the right vertical axis. (b) Zoom-in at the same curves as in (a) for a single collapse event.

value h is determined from simulations as

$$\mathcal{P}(h) = \frac{\int \delta(|\psi(x, t)| - h) dx dt}{\int dx dt} \quad (22)$$

and, as shown in Figure 12b, it is again very close to the Gaussian distribution. Large fluctuations of $|\psi|$ are however, quite different from the Gaussian distribution and have power-like tails as shown in Figure 12c at log-log scale. From comparison of Figures 12a, b and c we conclude that the fit to the Gaussian distribution works very well for $|\psi| \lesssim 8$ which can be interpreted as the superposition of numerous almost linear waves. For $|\psi| \gtrsim 10$ the PDF has a power law-like dependence which can be

FIG. 12: (Color online) PDFs for simulations with $a = 1, c = 1, b = 10^4, \epsilon = 2 \cdot 10^{-3}$. (a) PDF $\mathcal{P}_r(h_r)$ for $h_r = \text{Re}(\psi)$. Solid blue line represents numerical result and dotted blue line is for Gaussian distribution $(2\pi)^{-1/2} h_0^{-1} e^{-h^2/(2h_0^2)}$ plotted for comparison. Here the variance $h_0^2 = 5.85$ is obtained from the simulation. (b) PDF $\mathcal{P}(h)$ of $h = |\psi|$ at linear scale. Solid blue line shows numerical result and dotted blue line is Gaussian distribution $h_0^{-2} h e^{-h^2/(2h_0^2)}$, where h_0^2 is the same variance as in (a). (c) PDF $\mathcal{P}(h)$ of $h = |\psi|$ at log-log scale. Solid blue line shows numerical result and dotted blue line is the Gaussian distribution as in (b). Thick solid red line shows h^{-8} law for comparison.

FIG. 13: (Color online) (a) PDF $\mathcal{P}(h)$ of $h = |\psi|$ for "k-limited" deterministic forcing (6), (15) with $k_{cutoff} = 10\pi$. Parameters are $a = c = 1, b_0 = 10^4, \epsilon = 2 \cdot 10^{-3}$. (b) PDF $\mathcal{P}(h)$ of $h = |\psi|$ for random forcing with parameters $a = c = 1, \epsilon = 10^{-3}, l_c = 0.02, b_g = 12500$.

roughly estimated as $\sim h^{-8}$ and which indicates intermittency of the optical turbulence [25].

Figure 13a shows the PDF $\mathcal{P}(h)$ for RQNLS with the "k-limited" deterministic forcing (6), (15) and Figure 13b shows the PDF $\mathcal{P}(h)$ for RQNLS with the random forcing (8). It is seen that both of these cases have the same type of power-like tails as in Figure 12c. Thus, the power-like tails are universal for RQNLS for $\epsilon \ll 1$ and independent of the type of forcing indicating the universal turbulent behavior.

In order to characterize the relevance of linear and nonlinear dissipation in PDF $\mathcal{P}(h)$, we consider the different parameter values for a and c while fixing ϵ and b . Figure 14a shows $\mathcal{P}(h)$ for fixed nonlinear dissipation $c = 1$

and different values of the linear dissipation coefficient a . As a decreases, the slope of PDF tail becomes steeper deviating from h^{-8} power law. For $a < 0.1$, we observe that the shape of $\mathcal{P}(h)$ tail is very close to the case of $a = 0.1$. Figure 14b shows $\mathcal{P}(h)$ for fixed linear dissipation $a = 1$ and variable c . The PDF tail again deviates from h^{-8} power law as c decreases. The change of tail is more significant at large amplitudes h . As c becomes smaller, high amplitude collapses occur more often, e.g., for $c \sim 0.05$, we frequently observe collapses with amplitude ≥ 500 . In contrast, if we change ϵ only, then the tails of $\mathcal{P}(h)$ behave similarly for small $\epsilon \lesssim 3 \cdot 10^{-3}$ except very large values of h as shown in Figure 14c.

We also study the sensitivity of $\mathcal{P}(h)$ to the change of amplification amplitude b . Figure 15 shows that a height of the maximum of $\mathcal{P}(h)$ decreases with the increase of b while the position of the maximum $h = h_0$ shifts to the right indicating the increase of the average amplitude $\langle |\psi|^2 \rangle$ (see also Figure 5). To stress this feature we focus in Figure 15 on a smaller domain in h and compare with previous figures, while for larger h the tails of $\mathcal{P}(h)$ behave similar for different b up to the normalization constant.

B. Power law-like tails of PDF

We now show that the power-like tail of $\mathcal{P}(h)$ results from the near-singular collapsing events. This approach dates back to the idea of describing strong turbulence in the Navier-Stokes equations through singularities of the Euler equations [22]. Unfortunately, this hydrodynamic problem remains unsolved. The forced Burgers equation remains as the only example of an analytical description of strong turbulence in which the tail of the PDF for negative gradients follows a well established $(-7/2)$ power law [23], dominated by the dynamics of near-singular shocks. Another example of the analytical description of the intermittency is a randomly advected passive scalar which is the example of the turbulent transport described by linear equations [35].

As a first step we calculate the contribution to the PDF from individual collapse events. As shown in Figure 8, the filament amplitude $|\psi|_{max}$ rapidly decays after reaching $|\psi|_{maxmax}$ at $t = t_{max}$. Thus, we neglect the contribution to $\mathcal{P}(h)$ from $t \gtrsim t_{max}$ in calculating the contribution of the individual filament to $\mathcal{P}(h)$. We define the conditional probability $\mathcal{P}(h|h_{max})$ for contribution to PDF from the collapse event with $|\psi|_{maxmax} \equiv h_{max}$

FIG. 14: (Color online) PDF $\mathcal{P}(h)$ of $h = |\psi|$. (a) Parameters are $\epsilon = 2 \cdot 10^{-3}$, $c = 1$, $b = 10^4$, $a = 0.05$ (dotted), $a = 0.1$ (dashed), $a = 0.5$ (dashed-dotted), $a = 1$ (solid). (b) Parameters are $\epsilon = 2 \cdot 10^{-3}$, $a = 1$, $b = 10^4$, $c = 0.1$ (dashed), $c = 0.5$ (dashed-dotted), $c = 1$ (solid). (c) Parameters are $a = 1$, $c = 1$, $b = 10^4$, $\epsilon = 10^{-3}$ (solid), $\epsilon = 2 \cdot 10^{-3}$ (dashed-dotted), $\epsilon = 5 \cdot 10^{-3}$ (dashed). Thick solid line shows h^{-8} power law in all Figures.

FIG. 15: (Color online) Zoom-in of PDF $\mathcal{P}(h)$ on the range of small $h = |\psi|$. Parameters are $\epsilon = 2 \cdot 10^{-3}$, $a = c = 1$, $b = 2 \cdot 10^3$ (solid), $b = 10^4$ (dashed), $b = 5 \cdot 10^4$ (dashed-dotted).

and use (16), (17), (20) and (22) as follows

$$\begin{aligned} \mathcal{P}(h|h_{max}) &\propto \int_0^{t_{max}} dt \int dx \delta\left(h - \frac{1}{L(t)^{1/2}} R_0\left(\frac{x}{L(z)}\right)\right) \\ &\propto \int d\rho \int_0^{L(t_{max})} \frac{dL L^2}{\gamma} \delta\left(h - \frac{1}{L(t)^{1/2}} R_0(\rho)\right) \\ &\simeq \int \frac{d\rho}{\langle\gamma\rangle h^7} [R_0(\rho)]^6 \Theta\left(\frac{R_0(0)}{L(t_{max})^{1/2}} - h\right) \\ &= \text{Const } h^{-7} \Theta(h_{max} - h), \end{aligned} \quad (23)$$

where $h_{max} = R_0(0)/L(t_{max})^{1/2} = 3^{1/4}/L(t_{max})^{1/2}$, and $\Theta(x)$ is the Heaviside step function. Here, we have changed the integration variable from t to L and approximated $\gamma(t)$ under the integral by its average value $\langle\gamma\rangle$ as $\gamma(t) \simeq \langle\gamma\rangle \sim 0.5$. This approximation is valid for $t \lesssim t_{max}$ outside the neighborhood of $t = t_{max}$ as seen in Figure 10.

As a second step we calculate $\mathcal{P}(h)$ by integration over all values of h_{max} using equation (23) as follows

$$\begin{aligned} \mathcal{P}(h) &= \int dh_{max} \mathcal{P}(h|h_{max}) \mathcal{P}_{max}(h_{max}) \\ &\simeq \text{Const } h^{-7} \int dh_{max} \Theta(h_{max} - h) \mathcal{P}_{max}(h_{max}) \\ &= \text{Const } h^{-7} H_{max}(h), \end{aligned} \quad (24)$$

where $\mathcal{P}_{max}(h_{max})$ is the PDF for $h_{max} = |\psi|_{maxmax}$ and $H_{max}(h) \equiv \int_h^\infty \mathcal{P}_{max}(h_{max}) dh_{max}$ is the cumulative probability for $|\psi|_{maxmax} > h$.

Figures 16a and 16b show $H_{max}(h_{max})$ for different values of parameters. Each curve is calculated after the system reaches the statistical steady using more than

10^3 collapse events with $h_{max} > 10$. We verified that the increase of the number of collapse event (i.e., increase of the total simulation time) does not change these curves in any significant way. Figure 16a shows that power-like dependence h_{max}^{-1} for $H_{max}(h_{max})$ if exist at all, quickly disappear with the increase of ϵ . Figure 16b shows that $H_{max}(h_{max})$ shows that power-like dependence h_{max}^{-1} shifts to larger values h_{max} with the decrease of a . Generally, we see from Figures 16a and 16b that for a wide range of parameters, including the decrease of ϵ , the dependence of $H_{max}(h_{max})$ cannot be approximated as $\propto (h_{max})^{-1}$. The assumption of $H_{max}(h_{max}) \propto (h_{max})^{-1}$ comes from (24) and the rough estimate that $\mathcal{P}(h) \propto h^{-8}$ as in thick solid red line of Figure 12c. We conclude that this conjecture, first made in [27], appears to be incorrect and h^{-8} is only a very crude approximation for $\mathcal{P}(h)$.

We now verify that the equation (24) is correct one, which justifies the assumptions used in (23) and (24). Figures 17a, 17b and 17c compare $\mathcal{P}(h)$ from simulations (solid blue lines) with the prediction of the equation (24) (red circles), where $H_{max}(h_{max})$ is obtained numerically and shown in Figure 16. Also Figure 16 shows that for $h \gtrsim 20$ the equation (24) appears to be much better fit of $\mathcal{P}(h)$ compare with h^{-8} power law. The normalization constant in the equation (24) was chosen to fit $\mathcal{P}(h)$ at large h . The deviation of (24) from $\mathcal{P}(h)$ for $h \lesssim 20$ is perhaps due to the decaying of the large amplitude collapse events into large amplitude waves (as e.g. in Figure 9c). This explanation is consistent with the increase of that deviation for smaller values of a as in Figures 17c because the decrease of a causes these large amplitudes almost linear waves to live longer before dissipating, thus giving a bigger contribution into $\mathcal{P}(h)$. We also conclude from Figures 17a, 17b and 17c that because such deviation is insignificant for $h \gtrsim 20$, the contribution of large amplitude waves is not important in that range of h . The good agreement between $\mathcal{P}(h)$ and the equation (24) justifies the assumptions used in derivation of the equation (24) as well as it shows that the intermittency of optical turbulence of RQNL (5) is solely due to collapse dynamics. We also conclude that while h^{-8} power law appears to be an intermediate fit at best, the equation (24) works for all values of parameters of RQNL we tested.

V. NUMERICAL SIMULATIONS OF 1D RQNL

In this section we provide detailed description of the numerical methods used to produce the simulations described above. We conduct numerical simulation of RQNL (5) by employing a version of the fourth order split-step method [36] (outlined below) for deterministic forcing as well as the second order split-step method for random forcing. For efficient computation, we adaptively change the spatial grid size Δx during the time evolution in the spatial domain $-0.5 \leq x \leq 0.5$. Specifically, if the

FIG. 16: (Color online) Cumulative probability $H_{\max}(h_{\max})$ for $h_{\max} = |\psi|_{\max}$ and deterministic forcing with $c = 1, b = 10^4$. (a) Parameters are $a = 1, \epsilon = 5 \cdot 10^{-3}$ (solid), $\epsilon = 2 \cdot 10^{-3}$ (dashed-dotted), $\epsilon = 10^{-3}$ (dashed). (b) Parameters are $\epsilon = 2 \cdot 10^{-3}, a = 0.05$ (solid), $a = 0.1$ (dashed-dotted), $a = 0.5$ (dashed), $a = 1$ (dotted). Thick solid red line shows $h_{\max}^{-1}$ power law for comparison in both figures.

amplitudes of Fourier components of solution, $|\psi_k|$, at high frequencies exceed $10^{-10} \max_k |\psi_k|$, we reduce Δx by adding more Fourier modes to the system. If the amplitudes of high frequency modes are below the criteria, we increase Δx by removing some of the existing Fourier modes. The numerical time step, Δt , is also updated as Δx changes, which follows the relation $\Delta t k_{\max}^2 = q_0 \pi$. Here $k_{\max} = \pi/\Delta x$ is the maximum wavenumber determined by the discretization and we choose the constant factor q_0 small enough to avoid numerical instability. The numerical instability occurs if the change of phase $\Delta\phi = \Delta t k_{\max}^2$ of the highest Fourier harmonics

FIG. 17: (Color online) Solid curve represents PDF $\mathcal{P}(h)$ for $h = |\psi|$, and dashed line shows h^{-8} power law. Circles correspond to the rhs of equation (24). (a) Parameters are $\epsilon = 2 \cdot 10^{-3}, a = c = 1, b = 10^4$. (b) Parameters are $\epsilon = 10^{-3}, a = c = 1, b = 10^4$. (c) Parameters are $\epsilon = 2 \cdot 10^{-3}, a = 0.5, c = 1, b = 10^4$.

k_{max} from the linear term of RQNLS at one discrete time step Δt is above $\pi/2$: $\Delta\phi \geq \pi/2$. In that case a mixing of the Fourier harmonics in the quintic nonlinear term in RQNLS can produce artificial (discretization-caused) resonance from the condition $4\Delta\phi = 2\pi$. It implies that to avoid the instability we have to choose $q_0 < 1/2$. In simulation we typically choose $q_0 = 0.2$ which allows to avoid instability as well as insures high accuracy in time stepping. The initial condition of our numerical simulation is a random field with small amplitude whose maximum value is about 1.6.

A. Fourth order Split-Step scheme

We write equation (5) formally in the form of

$$\psi_t = (\hat{L} + \hat{N})\psi, \quad (25)$$

where $\hat{L}$ is the linear and $\hat{N}$ is the nonlinear operators, defined by

$$\hat{L}\psi = i(1 - ia\epsilon)\nabla^2\psi + \epsilon\phi, \quad (26)$$

$$\hat{N}\psi = i(1 + ic\epsilon)|\psi|^4\psi. \quad (27)$$

Separately both (26) and (27) can be solved very efficiently. Here, we approximate the exact solution $\psi(t_0 + \Delta t) = e^{\Delta t(\hat{N} + \hat{L})}\psi(t_0)$ of (25) over one segment from t_0 to $t_0 + \Delta t$ by the following expression

$$\begin{aligned} \psi(t_0 + \Delta t) &= e^{c_4\Delta t\hat{N}}e^{d_3\Delta t\hat{L}}e^{c_3\Delta t\hat{N}}e^{d_2\Delta t\hat{L}}e^{c_2\Delta t\hat{N}} \\ &\times e^{d_1\Delta t\hat{L}}e^{c_1\Delta t\hat{N}}\psi(t_0), \end{aligned} \quad (28)$$

where

$$\begin{aligned} c_1 &= \frac{1}{2(2-2^{1/3})}, & c_2 &= \frac{1-2^{1/3}}{2(2-2^{1/3})}, \\ c_3 &= c_2, & c_4 &= c_1, \\ d_1 &= \frac{1}{2-2^{1/3}}, & d_2 &= \frac{-2^{1/3}}{2-2^{1/3}}, & d_3 &= d_1. \end{aligned} \quad (29)$$

The split-step expression (28), (29) is of the fourth order accurate and it is a straightforward generalization of the forth order symplectic integration of [36] to non-Hamiltonian systems.

The linear part $e^{\Delta t\hat{L}}$ of the operator splitting can be efficiently calculated by using the Fast Fourier Transform algorithm (FFT) for the deterministic forcing (6). For the stochastic forcing (8) the equation (26) has a form of the inhomogeneous linear differential equation. Homogeneous part of that equation we solve again using FFT while the contribution of the inhomogeneous term is obtained by the numerical integration over t for each x . We use the trapezoidal rule for the integration which makes the scheme the second order in the random noise case. Therefore, instead of the fourth-order split-step algorithm (28), we use the standard second order split-step algorithm $\psi(t_0 + \Delta t) = e^{(1/2)\Delta t\hat{L}}e^{\Delta t\hat{N}}e^{(1/2)\Delta t\hat{L}}\psi(t_0)$, in the random noise case.

The nonlinear part $e^{\Delta t\hat{N}}$ of the operator splitting can be solved exactly as follows. Denote the solution of the nonlinear part of RQNLS as $\psi^{\hat{N}}$. It means that $\psi^{\hat{N}}(t_0 + \Delta t) = e^{\Delta t\hat{N}}\psi^{\hat{N}}(t_0)$. According to RQNLS, $\psi^{\hat{N}}$ satisfies the following equation:

$$\partial_t \psi^{\hat{N}} = (-c\epsilon + i)|\psi^{\hat{N}}|^4\psi^{\hat{N}}. \quad (30)$$

It implies that

$$\frac{d}{dt}|\psi^{\hat{N}}|^2 = -2c\epsilon|\psi^{\hat{N}}|^6, \quad (31)$$

and hence, we find

$$|\psi^{\hat{N}}(t)|^2 = 0, \quad \text{if } |\psi^{\hat{N}}(t_0)|^2 = 0, \quad (32)$$

$$|\psi^{\hat{N}}(t)|^2 = [4c\epsilon(t - t_0) + |\psi^{\hat{N}}(t_0)|^4]^{-\frac{1}{2}}, \text{ otherwise.} \quad (33)$$

Using equations (32),(33), we obtain the explicit solution of equation (30),

$$\begin{aligned} \psi^{\hat{N}}(t_0 + \Delta t) &= \exp \left[\frac{-c\epsilon + i}{4c\epsilon} \ln[4c\epsilon\Delta t|\psi^{\hat{N}}(t_0)|^4 + 1] \right] \\ &\times \psi^{\hat{N}}(t_0). \end{aligned} \quad (34)$$

In the case of random forcing (8), at each time step we independently generate the random variable $\xi(x)$ by the Ornstein-Uhlenbeck process [34] as a function of x with zero mean and correlation length $l_c = 0.02$ that satisfies a stochastic differential equation, $\frac{d\xi}{dx} = -l_c^{-1}\xi(x) + \sigma(\Delta t)^{-1/2}\frac{dW(x)}{dx}$, where $\sigma > 0$ and $W(x)$ denotes the Wiener process. This Ornstein-Uhlenbeck process yields an exponential correlation function (9) with $b_g = \sigma^2 l_c/2$. Here the factor $(\Delta t)^{-1/2}$ multiplying dW/dx ensures δ -correlation of ξ in time for $\Delta t \rightarrow 0$.

VI. CONCLUSION

In this paper we studied the strong turbulence in 1D RQNLS (5). In the statistical steady-state (the state of developed turbulence) the dynamical balance is achieved between forcing which pumps the number of particles N into the system and both linear and nonlinear dissipation. RQNLS has multiple collapse events randomly distributed in space and time. We found that in the state of developed turbulence the spatial and temporal correlation functions have universal forms independent of the particular values of parameters of RQNLS as well as independent of the type of forcing. In particular we considered the deterministic forcing with variable k -dependence as well as random forcing. We found that the relation between the correlation length and the average amplitude p_0 has a universal form (14) determined by the modulational instability scale.

PDF $\mathcal{P}(h)$ of amplitude fluctuations is well approximated by the Gaussian distribution for $h \lesssim 3p_0$. In contrast, $\mathcal{P}(h)$ for $h \gtrsim 4p_0$ has the strongly non-Gaussian tail

with power-like behavior characterizing intermittency of strong collapse-dominated turbulence. This tail is determined by the equation (24) which includes the contribution $\propto h^{-7}$ from the universal spatio-temporal form of the collapse events as well as the contribution from the cumulative probability $H_{max}(h)$, the probability of the maximum amplitude of collapse event that exceeds h . We show that $H_{max}(h)$ is not universal and depends on the parameters of RQNLS. For some range of parameters $H_{max}(h)$ can be roughly estimated as $\propto h^{-1}$ but it appears to be an intermediate asymptotic at best

An important problem to be studied in future work is to determine the analytical form of $H_{max}(h)$ from the parameters of RQNLS. This is a challenging problem and

will require calculation of the optimal fluctuations of the background which seeds new collapses. Moreover, it will be necessary to find the relation between the size of such optimal fluctuation and the maximum collapse event amplitude $|\psi|_{maxmax}$.
